A cluster centers initialization method for clustering categorical data

Liang Bai, Jiye Liang, Chuangyin Dang, Fuyuan Cao

1. Introduction

Clustering is a process of grouping a set of objects into clusters so that the objects in the same cluster have high similarity but are very dissimilar with objects in other clusters. Various types of clustering methods have been proposed and developed, see, for instance (Jain & Dubes, 1988). Clustering algorithms in the literature can generally be classified into two types: hierarchical clustering and partitional clustering. Hierarchical clustering algorithms, essentially heuristic procedures, produce a hierarchy of partitions of the set of observations according to an agglomerative strategy or to a divisive one. Partitional clustering algorithms, in general, assume a given number of clusters and, essentially, seek the optimization of an objective function measuring the homogeneity within the clusters and/or the separation between the clusters.

The k-means algorithm (Anderberg, 1973; Ball & Hall, 1967; MacQueen, 1967; Jain & Dubes, 1988) is a well known partitional clustering algorithm which is widely used in real world applications such as marketing research and data mining to cluster very large data sets due to their efficiency. In 1997 Huang (1997, 1998), extended the k-means algorithm to propose the k-modes algorithm whose extensions have removed the numeric-only limitation of the k-means algorithm and enable the k-means clustering process to be used to efficiently cluster large categorical data sets from real world databases. Since first published, the k-modes algorithm has become a popular technique in solving categorical data clustering problems in different application domains (Andreopoulos, An, & Wang, 2005).

The k-means algorithm and the k-modes algorithm use alternating minimization methods to solve non convex optimization problems in finding cluster solutions (Jain & Dubes, 1988). These algorithms require a set of initial cluster centers to start and often end up with different clustering results from different sets of initial cluster centers. Therefore, these algorithms are very sensitive to the initial cluster centers. Usually, these algorithms are run with different initial guesses of cluster centers, and the results are compared in order to determine the best clustering results. One way is to select the clustering results with the least objective function value formulated in these algorithms, see, for instance (Huang, Ng, Rong, & Li, 2005). In addition, cluster validation techniques can be employed to select the best clustering result, see, for instance (Jain & Dubes, 1988). Other approaches have been proposed and studied to address this issue by using a better initial seed value selection for the k-means algorithm (Arthur & Vassilvitskii, 2007; Babu & Murty, 1993; Brendan & Delbert, 2007; Bradley, Mangasarian, & Street, 1997; Bradley & Fayyad, 1998; Khan & Ahmad, 2004; Krishna & Murty, 1999; Laszlo & Mukherjee, 2006, 2007; Pen, Lozano, & Larraaga, 1999). For example, some experts (Babu & Murty, 1993; Krishna & Murty, 1999; Laszlo & Mukherjee, 2006, 2007) used genetic algorithm to obtain the good initial cluster centers. Arthur and Vassilvitskii (2007) proposed and studied a careful seeding for initial cluster centers to improve clustering results. However, due to lack of intuitive geometry for categorical data, the techniques used in cluster centers initialization for numerical data are not applicable to categorical data. To date, few researches...
are concerned for cluster centers initialization for categorical data. However, due to the fact that large categorical data sets exist in many applications, it has been widely recognized that directly clustering the raw categorical data is important. Examples include environmental data analysis (Wrigley, 1985), market basket data analysis (Aggarwal, Magdalena, & Yu, 2002), DNA or protein sequence analysis (Baxevanis & Ouellette, 2001), text mining (Wang & Karypis, 2006), and computer security (Barbara & Jajodia, 2002). Therefore, how to select initial cluster centers for clustering categorical data become an important research question. The \( k \)-centers clustering technique.

Huang in Huang (1998) suggested to select the first \( k \) distinct objects from the data set as the initial \( k \) modes or assign the most frequent categories equally to the initial \( k \) modes. Though the methods are to make the initial modes diverse, an uniform criteria is not given for selecting \( k \) initial modes in Huang (1998). Sun, Zhu, and Chen (2002) introduces an initialization method which is based on the frame of refining. This method presents a study on applying Bradley’s iterative initial-point refinement algorithm (Bradley & Fayyad, 1998) to the \( k \)-modes clustering, but its time complexity is high and the parameters of this method are plenty which need to be asserted in advance. In Coolcat algorithm (Barbara, Couto, & Li, 2002), the MaxMin distances method is used to find the \( k \) most dissimilar objects from the data set as initial seeds. However, the method only considers the distance between the data objects, by which outliers maybe be selected. Cao, Liang, and Bai (2009) and Wu, Jiang, and Huang (2007) integrated the distance and the density together to propose a cluster centers initialization method, respectively. The difference between the two methods is the definition of the density of an object. Wu used the total distance between an object and all objects from data set as the density of the object. Due to the fact that the time complexity of calculating the densities of all objects is \( O(n^2) \), it limits the process in a sub-sample data set and uses a refining framework. But this method needs to randomly select sub-sample, so the sole clustering result can not be guaranteed. Cao et al. (2009) defined the density of an object based on frequency of attribute values. In this paper, we prove that Cao’s density is equivalent to Wu’s density, which means that Cao’s method is equivalent to Wu’s method. Although the two methods can avoid to select outliers as the cluster centers by the density, they have some shortcomings: (1) The object with the maximum density is taken as the first cluster center. Due to the fact that they only considered the factor of density in the selection of the first cluster center, it is possible that the selected object is a boundary point among clusters, which is proved in this paper; (2) One real object in a cluster is selected as the cluster center. But in most cases, the center of a cluster is not a real object but a virtual object, which means that a real object could not sufficiently represent the cluster. In summary, there are no universally accepted method for obtaining initial cluster centers currently. Hence, it is very necessary to propose a new initialization method for categorical data which overcomes shortcomings of the existing initialization methods.

In the paper, we propose a novel cluster centers initialization method. We use the distances between objects and the center of the whole data set to avoid selecting the boundary objects among clusters as the first cluster center. In this method, an object is selected not as an initial cluster center but as a cluster exemplar. We integrate the cluster exemplar and the neighbor objects around it together to construct the candidates of the initial cluster center, and define some criteria to select initial cluster centers from the candidates. The proposed initialization method is used along with the \( k \)-modes algorithm. The time complexity of the method is analyzed. The comparisons with other methods illustrate the effectiveness of this approach.

The outline of the rest of this paper is as follows. Section 2 introduces the \( k \)-modes algorithm. In Section 3, a new initialization method is proposed. Section 4 demonstrates the effectiveness and scalability of the new initialization method. General discussion and the conclusions of this work follow in Section 5.

2. The \( k \)-modes algorithm

As we know, the structural data are stored in a table, where each row (tuple) represents facts about an object. A data table is also called an information system in rough set theory (Liang & Li, 2005, Liang, Wang, & Qian, 2009; Pawlak, 1991; Qian, Liang, Pedrycz, & Dang, 2010). Data in the real world usually contains categorical attributes (Gowda & Diday, 1999). More formally, a categorical data table is defined as a quadruple \( IS = (U, A, V, f) \), where:

- (1) \( U \) is the nonempty set of objects, called a universe.
- (2) \( A \) is the nonempty set of attributes.
- (3) \( V \) is the union of attribute domains, i.e., \( V = \bigcup_{i \in A} V_i \) where \( V_i \) is the value domain of attribute \( a \) and it is finite and unordered, e.g., for any \( p, q \in V_a \), either \( p = q \) or \( p \neq q \).
- (4) \( f : U \times A \rightarrow V \) is an information function such that for any \( a \in A \) and \( x \in U, f(x, a) \in V_a \).

The objective of the \( k \)-modes algorithm is to cluster \( U \) into \( k \) clusters by minimizing the function

\[
F(W, Z) = \sum_{i=1}^{k} \sum_{l=1}^{n} \omega_l d(z_l, x_i)
\]

subject to

\[
\omega_l \in \{0, 1\}, \quad 1 \leq l \leq k, \quad 1 \leq i \leq n,
\]

\[
\sum_{l=1}^{k} \omega_l = 1, \quad 1 \leq i \leq n,
\]

and

\[
0 < \sum_{l=1}^{k} \omega_l < n, \quad 1 \leq l \leq k,
\]

where \( k(\leq n) \) is a known number of clusters. \( W = [c_{ab}] \) is a \( k \)-by-\( n \) matrix, \( c_{ab} \) indicates whether \( x_b \) belongs to the \( l \)th cluster for the \( k \)-modes algorithm, \( c_{ab} = 1 \) if \( x_b \) belongs to the \( l \)th cluster and 0 otherwise. \( Z = \{z_1, z_2, ..., z_k\} \), and \( z_l \) is the \( l \)th cluster center with the categorical attributes \( a_1, a_2, ..., a_n \).

To cluster categorical data, the \( k \)-modes algorithm (Huang, 1997, 1998) measures the distance between a cluster center and a categorical data object, and updates the cluster center at each iteration as follows:

The distance measure \( d(z_l, x_i) \) between a center \( z_l \) and a categorical data object \( x_i \) is defined as

\[
d(z_l, x_i) = \sum_{a \in A} \delta_l(a, z_l, x_i)
\]

where

\[
\delta_l(a, z_l, x_i) = \begin{cases} 1, & f(z_l, a) \neq f(x_i, a), \\ 0, & f(z_l, a) = f(x_i, a). \end{cases}
\]

It is easy to verify that the function \( d \) defines a metric space on the set of categorical objects. The \( l \)th cluster center \( z_l \) referred to as the \( l \)th mode, is updated as follows. Each \( f(z_l, a) \) for \( a \in A \) is updated. For the \( k \)-modes algorithm, \( f(z_l, a) \) satisfies the following criterion:

\[
\{ x_i \in U | f(x_i, a) = f(z_l, a), c_{al} = 1 \} = \max_{q \in V_a} \{ x_i \in U | f(x_i, a) = q, c_{al} = 1 \}.
\]

For the \( k \)-modes algorithm, \( W = [c_{ab}] \) is updated as

\[
c_{ab} = \begin{cases} 1, & \text{if } d(z_l, x_i) = \min_{1 \leq c \leq k} d(z_c, x_i), \\ 0, & \text{otherwise}. \end{cases}
\]
The whole process of the k-modes algorithm is described as follows (Huang, 1998):

Step 1. Choose an initial point $Z(1) \subseteq R$, where $R = V_{a_1} \times V_{a_2} \times \ldots \times V_{a_k}$. Determine $W(1)$ such that $F(W, Z(1))$ is minimized. Set $t = 1$.

Step 2. Determine $Z^{(t+1)}$ such that $F(W(1), Z^{(t+1)})$ is minimized. If $F(W(1), Z^{(t+1)}) = F(W(1), Z(1))$, then stop; otherwise goto Step 3.

Step 3. Determine $W^{(t+1)}$ such that $F(W^{(t+1)}, Z^{(t+1)})$ is minimized. If $F(W^{(t+1)}, Z^{(t+1)}) = F(W^{(t+1)}, Z^{(t+1)})$, then stop; otherwise set $t = t + 1$ and goto Step 2.

This procedure removes the numeric-only limitation of the k-means algorithm. However, the k-modes algorithm is the same as the k-means algorithm and is sensitive to initial cluster centers. To solve these problems, a new initialization method for categorical data is proposed in Section 3.

3. A new cluster centers initialization method

Currently, many approaches are proposed to measure the cohesiveness of a data object (Cao et al., 2009; Ester, Kriegel, Sander, & Xu, 1996; Wu et al., 2007). It is well known to use the total distance between a data object and all data objects to measure the density of the data object (Wu et al., 2007), because of its simple and no parameters. Hence, we decide to use the density to measure a point in $R$ where $R = V_{a_1} \times V_{a_2} \times \ldots \times V_{a_k}$. The definition is given as follows:

**Definition 1.** Let $IS = (U, A, V, f)$ be a categorical data table, $A = \{a_1, a_2, \ldots, a_i\}$, $R = V_{a_1} \times V_{a_2} \times \ldots \times V_{a_k}$. For any $x \in R$, the density of $x$ in $R$ is defined as:

$$Dens(x) = \frac{1}{|U|} \sum_{y \in U} d(x, y).$$

Obviously, we have $-|A| \leq Dens(x) \leq 0$. For any $y \in U$, if $d(x, y) = 0$, then $Dens(x) = 0$. If $d(x, y) = |A|$, then $Dens(x) = -|A|$.

By the definition of the density, we know that the time complexity of calculating the densities of $n$ objects is $O(|U| |A| n)$. Since the initialization method needs to calculate the densities of all data objects in the data set whose time complexity is $O(|U|^2 |A|)$, a working method has to optimize the density calculation.

**Proposition 1.** For any point $x \in R$, $Dens(x) = \sum_{a \in A} \left( \frac{|\{y \in U | f(x, a) = f(y, a)\}|}{|U|} - 1 \right)$.

**Proof.**

$$Dens(x) = \frac{1}{|U|} \sum_{y \in U} d(x, y) = \frac{1}{|U|} \sum_{a \in A} \sum_{y \in U} \delta_0(x, y)$$

$$= \frac{1}{|U|} \sum_{a \in A} \sum_{y \in U} \delta_0(x, y)$$

$$= \frac{1}{|U|} \sum_{a \in A} \left( |U| - |\{ y \in U | f(x, a) = f(y, a) \}| \right)$$

$$= \sum_{a \in A} \left( \frac{|\{ y \in U | f(x, a) = f(y, a) \}|}{|U|} - 1 \right).$$

This completes the proof. ☐

From the view of Proposition 1, we know the relation between the density and the frequencies of the attribute values, which prove that Cao’s density is equivalent to Wu’s density. For a given categorical data table, the number of every category of every categorical attribute is known. We first compute the frequency of every attribute value of every attribute and save these to a table. Next, we compute densities of data objects by the saved table. The method is described in Table 1. Since the time complexity of calculating frequencies of all values in the categorical attribute $a \in A$ is $O(|U| |V_a|)$, the time complexity of calculating densities of all data objects in a data table is $O(|U| |V|)$, where $|V| = \sum_{a \in A} |V_a|$. When the number of objects is large, $|V| \ll |U|$. Therefore, the method in Table 1 can be applied to large data sets for its linear time complexity with respect to the number of data objects.

**Proposition 2.** If $z \in R$ is a mode of $U$, then $Dens(z) = \max_{q \in V_a} Dens(x)$.

**Proof.** Let $z$ be a mode of $U$. From the definition of mode in Section 2, it follows that for each $a \in A$,

$$\{|x \in U | f(x, a) = f(z, a)\}| = \max_{q \in V_a} \{|x \in U | f(x, a) = q\},$$

then

$$Dens(z) = \max_{x \in U} Dens(x).$$

This completes the proof. ☐

According to Definition 1, we know that the more $Dens(x)$ is, if can be expressed in a graph, the more the number of objects around $x$ is, as well as the more possible $x$ may be a cluster center. So Wu et al. (2007) and Cao et al. (2009) selected the point with the maximum density as the first initial cluster center. However, the point also may be a boundary point among clusters. According to Proposition 2, we find that the $Dens(z)$ of the mode $z$ of $U$ is maximum. $z$ can be seen as a center point of $U$ which is similar to the mean of numerical data and reflects the common features in $U$. That means that the smaller the distance between a data object $x$ and $z$ is, the more $x$ may contain the common features of all clusters. When a data object $x$ contains common features of all clusters, $x$ may be a boundary point among clusters although $x$ may have high value of $Dens(x)$.

Let us consider the following example to demonstrate the problem. The synthetic data set in Table 2 is described with four categorical attributes $A_1$ (four categories: B, C, D, or F), $A_2$ (six categories: B, C, D, E, or G), $A_3$ (five categories: B, C, D, E, or F), and $A_4$ (six categories: B, C, D, E, or F), and there are three classes with their modes and their four objects.

We find that $x_4$ is a boundary point among clusters, although $Dens(x_4) = \max_{x \in D_1} Dens(x_4)$. Since $d(x_4, z_1) = \max_{x \in D_1} d(y, z_1)$, $x_4$ cannot reflect the characteristics of the class $D_1$ than other objects in $D_1$.

\( C \rightarrow C \rightarrow C \rightarrow C \)
\( x_0 \)          \( E \rightarrow E \rightarrow B \rightarrow E \)
\( x_0 \)          \( E \rightarrow E \rightarrow E \rightarrow F \)
\( x_0 \)          \( E \rightarrow E \rightarrow F \rightarrow D \)
\( x_0 \)          \( C \rightarrow B \rightarrow E \rightarrow D \)

The mode \( z_1 \) of the class \( D_3 \):
\( E \rightarrow E \rightarrow E \rightarrow E \)

Therefore, when computing the first cluster center, if the density of the objects is only taken into account, it is very possible that the boundary point among clusters is taken as a cluster center. To avoid the potential problem, first, we compute a mode \( z \) of \( U \). Since \( z \) reflects the common features in \( U \), if the smaller the distances between an object and \( z \) is, the more possible the object as a boundary point among clusters is. So we select the object with higher density and farther from \( z \). We combine the distance between the object and \( z \) with the density of the object together to measure the possibility of the object to be an exemplar of the first cluster. According Definition 2, we select a data object with maximum \( \text{Pos} \_\text{Exemplar}_{C_1}(x) \) as an exemplar of the first cluster.

**Definition 2.** Let \( IS = (U, A, V, f) \) be a categorical data table and \( z \in R \) be a mode of \( U \). For any \( x \in U \), the possibility of \( x \) to be an exemplar of the first cluster \( C_1 \) is defined as

\[
\text{Pos} \_\text{Exemplar}_{C_1}(x) = \text{Dens}(x) + d(x, z).
\]

Due to the fact that an object could not sufficiently represent a cluster, we take the selected object not as an initial cluster center but as an exemplar of a cluster. We integrate the information of the exemplar and its neighbor objects to construct the candidates and define some criteria to select points from the candidates as the initial cluster centers. In the following, we give the definition and method of constructing the candidates based on the selected exemplar. The time complexity of the method is analyzed.

**Definition 3.** Let \( IS = (U, A, V, f) \) be a categorical data table and \( x \in U \) be an exemplar of the \( l \)th cluster \( C_l \). \( CA_l \) to be a set of the candidate cluster centers of \( C_l \) is defined as

\[
CA_l = \{ca_1, \ldots, ca_m\},
\]

where \( ca_n \in R \) is a mode of the set \( Q_l = \{y \in U|d(y, x) \leq l\}, \ l \leq i \leq |A| \).

In Table 3, the method for computing \( CA_l \) is described where \( x \) is given. Table 3 shows that the time complexity of computing \( CA_l \) is \( O(|U||V|) \).

According to Definition 3, we know that if \( 1 \leq i < j \leq m, Q_i \subseteq Q_j \), which means that as the value of \( i \) increases, the number of the neighbor objects of the exemplar \( x \) contained by \( Q_i \) increases. In other words, \( ca_j \) contains more information of the neighbor objects than \( ca_i \). However, for the value of \( i \), bigger is not better. Because \( Q = U \) and \( ca_i \) is a mode of \( U \) when \( i = m \). That tells us that the excessive amount of objects contained by \( Q \) weakens the representability of \( ca_i \) to the exemplar \( x \). Therefore, we should integrate the partial neighbor objects of the exemplar. It is important to choose an appropriate \( ca_i \) from \( CA_l \).

Next, we define a criterion to select a point from the candidates as the first cluster center. From the candidates, we select a point which is with the higher density and farther from the mode \( z \) of \( U \) but closer to the exemplar. We give the explanations about the criterion that (1) the selected point with the higher density means that there are more objects around it; (2) the selected point farther from the mode \( z \) of \( U \) reduces the possibility to be boundary point among clusters; (3) the selected point closer to the exemplar means that it better represents the exemplar \( x \) in the cluster.

**Definition 4.** Let \( IS = (U, A, V, f) \) be a categorical data table, \( z \) be a mode of \( U, x \) be an exemplar of the first cluster \( C_1 \) and \( CA_0 \) be a set of the candidate cluster centers of \( C_1 \). For any \( y \in CA_0 \), the possibility of \( y \) to be a cluster center of \( C_1 \) is defined as

\[
\text{Pos} \_\text{center}_{C_1}(y) = \text{Dens}(y) + d(y, z) - d(y, x).
\]

The selection criterion of the rest cluster centers is different from the first cluster center. For selection of the rest cluster centers, we consider the distances between points and other selected cluster centers, instead of the distances between points and the mode \( z \) of \( U \). The larger the distances between the point and other selected cluster centers are, the more distinct the point is from other selected cluster centers. In the criterion, we do not consider the distance between the point and the mode \( z \) of \( U \), because we cannot ignore the fact that \( z \) also may be a cluster center in some situations, for example, the data set is imbalanced.

**Definition 5.** Let \( IS = (U, A, V, f) \) be a categorical data table and \( Z_l = \{z_1, z_2, \ldots, z_l\} \) be a set of the obtained cluster centers, where \( 0 < l < k \). For any \( x \in U \), the possibility of \( x \) to be an exemplar of the \( l + 1 \) cluster \( C_{l+1} \) is defined as

\[
\text{Pos} \_\text{Exemplar}_{C_{l+1}}(x) = \text{Dens}(x) + d(x, z_l) - d(x, z_{l+1}).
\]
From the candidates, we select a point as the cluster center which is with the higher density and farther from other selected cluster centers but closer to the exemplar.

**Definition 6.** Let \( IS = (U, A, V, f) \) be a categorical data table, \( Z_i = \{ z_1, z_2, \ldots, z_l \} \) be a set of the chosen cluster centers, where \( i < k, k \) be an exemplar of the \( i + 1 \)th cluster \( C_{i+1} \) and \( CA_k \) be a set of the candidate cluster centers of \( C_i \). For any \( y \in CA_k \), the possibility of \( y \) to be a cluster center of \( C_{i+1} \) is defined as

\[
\text{Pos}_{\text{center}}_{C_{i+1}}(y) = \text{Dens}(y) + \min_{j=1}^{l} d(y, z_j) - d(y, x).
\]

In the following, a new initialization method for categorical data is described in Table 4.

The time complexity of the proposed initialization method is composed of two parts. First, we obtain a mode of \( U \), and calculate densities of all objects in \( U \), whose time complexity is \( O(|U|) \). Second, the computing of the initial cluster centers will take \( O(|U|k^2 + |U| |V|k + |A|k^2) \) steps. Therefore, the whole time complexity of the proposed method is \( O(|U| + |U|k^2 + |U| |V|k + |A|k^2) \). In Table 5, the time complexities of Cao’s methods and the proposed method are showed. The comparison illustrates that the proposed method requires slightly more computational times than Cao’s method. It is an expected outcome since the construction and selection of candidates requires some additional arithmetic operations. However, according to the analysis of the time complexity, the computational complexity of the proposed method is still scalable which is linear with respect to the number of data objects, i.e., it can cluster large categorical data efficiently.

We use the above example in Table 2 to compare it with Cao’s method and demonstrate performance of the proposed initialization method. Table 6 shows the initial cluster centers obtained using Cao’s method and the proposed method. We use the \( k \)-modes algorithm with the different initial cluster centers to cluster the data set in Table 2. In Table 7, the clustering results are displayed. Tables 6 and 7 illustrate that the proposed method can obtain the better initial cluster centers than Cao’s method for clustering the data set in Table 2.

### 4. Experimental analysis

In this section, in order to evaluate the performance and scalability of the proposed initialization method, some standard data sets are downloaded from the UCI Machine Learning Repository (2010). All missing attribute values are treated as special values. In the performance analysis, we introduce an evaluation method (Yang, 1999) and compare the clustering results of the \( k \)-modes algorithm based on different initialization methods including random initialization method, Cao’s method and the proposed method. At random initialization method, we carried out 100 runs of the \( k \)-modes algorithm on these standard data sets, respectively. In the scalability analysis, we test the proposed algorithm in connect-4 data set from UCI (UCI Machine Learning Repository, 2010).

#### 4.1. Performance analysis

To evaluate the performance of clustering results, an evaluation method is introduced (Yang, 1999). If a data set contains \( k \) classes for a given clustering, let \( \alpha_i \) denote the number of data objects that are correctly assigned to class \( C_i \). Let \( \beta_i \) denote the data objects that are incorrectly assigned to class \( C_i \), and let \( \gamma_i \) denote the data objects that are incorrectly rejected from the class \( C_i \). The accuracy, precision and recall are defined as follow:

\[
\text{AC} = \frac{\sum_{i=1}^{k} \alpha_i}{|U|},
\]

\[
\text{PR} = \frac{\sum_{i=1}^{k} \alpha_i}{\sum_{i=1}^{k} \alpha_i + \beta_i},
\]

\[
\text{RE} = \frac{\sum_{i=1}^{k} \alpha_i}{\sum_{i=1}^{k} \alpha_i + \gamma_i},
\]

respectively.

We present comparative results of clustering on soybean data, lung cancer data, zoo data, dermatology data, breast cancer data and mushroom data, respectively.
4.1.1. Soybean data
The soybean data set has 47 records, each of which is described by 35 attributes. Each record is labeled as one of the four diseases: Diaporthe Stem Canker, Charcoal Rot, Rhizoctonia Root Rot, and Phytophthora Rot. Except for Phytophthora Rot which has 17 records, all other diseases have 10 records each. The cluster recovery result of the \( k \)-modes algorithm with the proposed method on the soybean data is summarized in Table 8. The comparison of clustering results of different initialization methods on the soybean data is presented in Table 9.

</tbody>
</table>

4.1.1. Soybean data
The soybean data set has 47 records, each of which is described by 35 attributes. Each record is labeled as one of the four diseases:
4.1.2. Lung cancer data
Lung cancer data set contains 32 instances described by 56 categorical attributes. The data set has three classes. The cluster recovery result of the k-modes algorithm with the proposed method on the lung cancer data is summarized in Table 10. The comparison of clustering results of different initialization methods on the lung cancer data is presented in Table 11.

4.1.3. Zoo data
Zoo data set contains 101 elements described by 17 Boolean-valued attributes and 1 type attribute. Data set with 101 Elements belong to seven classes. The cluster recovery result of the k-modes algorithm with the proposed method on the zoo data is summarized in Table 12. The comparison of clustering results of different initialization methods on the zoo data is presented in Table 13.

4.1.4. Dermatology data
Dermatology data set contains 366 elements and 33 categorical attributes. It has six clusters: psoriasis (112 data objects), seborrheic dermatitis (61 data objects), lichen planus (72 data objects), pityriasis rosea (49 data objects), chronic dermatitis (52 data objects) and pityriasis rubra pilaris (20 data objects). The cluster recovery result of the k-modes algorithm with the proposed method on the dermatology data is summarized in Table 14. The comparison of clustering results of different initialization methods on the dermatology data is presented in Table 15.

4.1.5. Breast cancer data
Breast cancer data set consists of 699 data objects and 9 categorical attributes. It has two clusters Benign (458 data objects), Malignant (241 data objects). The cluster recovery result of the k-modes algorithm with the proposed method on the breast cancer data is summarized in Table 16. The comparison of clustering results of different initialization methods on the breast cancer data is presented in Table 17.

4.1.6. Mushroom data
Mushroom data set consists of 8124 data objects and 23 categorical attributes. Each object belongs to one of two classes, edible (4208 objects) and poisonous (3916 objects). The cluster recovery result of the k-modes algorithm with the proposed method on the mushroom data is summarized in Table 18. The comparison of clustering results of different initialization methods on the mushroom data is presented in Table 19.

From the above experiential results, for the k-modes algorithm, we can see that the proposed method is superior to Cao’s method and random initialization method with respect to AC, PR, RE, respectively.

4.2. Scalability analysis
To test the scalability of the new algorithm, we choose Connect-4 data set from UCI. The data set contains 67,557 objects and 42 categorical attributes. It has three class: win (44,473), loss (16,635) and draw (6449). The computational results are performed by using a machine with an Intel Q9400 and 2G RAM. The computational times of the proposed algorithm are plotted against the number of objects, attributes and clusters, while the other corresponding parameters are fixed.

Fig. 1a shows the computational times against the number of objects, while the number of attributes is 42 and the number of clusters is 3. Fig. 1b shows the computational times against the number of attributes, while the number of clusters is 3 and the number of objects is 30,000. Fig. 1c shows the computational times against the number of clusters, while the number of attributes is 42 and the number of objects is 30,000. According to the figures, we can see that the proposed method is scalable, i.e., it can get the initial cluster centers of categorical data efficiently.

5. Conclusions
Categorical data are ubiquitous in real-world databases. The development of the k-modes algorithm was motivated to solve this problem. However, the clustering algorithm need to rerun many times with different initializations in an attempt to find a good solution. Moreover, this works well only when the number of clusters is small and chances are good that at least one random initialization is close to a good solution. In this paper, a new initialization method for categorical data clustering has been proposed by taking into account the distance between the objects and the density of the object and overcomes shortcomings of the existing initialization methods. Furthermore, the time complexity of the proposed method has been analyzed. We tested the proposed method using seven real world data sets from UCI Machine Learning Repository and experimental results have shown that the proposed method is superior to other initialization methods in the k-modes algorithm.
